VALUING COMPANIES WITH A FIXED BOOK-VALUE LEVERAGE RATIO

Pablo Fernández*

* Professor of Financial Management, PricewaterhouseCoopers Chair of Finance, IESE
The CIIF, International Center for Financial Research, is an interdisciplinary center with an international outlook and a focus on teaching and research in finance. It was created at the beginning of 1992 to channel the financial research interests of a multidisciplinary group of professors at IESE Business School and has established itself as a nucleus of study within the School’s activities.

Ten years on, our chief objectives remain the same:

- Find answers to the questions that confront the owners and managers of finance companies and the financial directors of all kinds of companies in the performance of their duties
- Develop new tools for financial management
- Study in depth the changes that occur in the market and their effects on the financial dimension of business activity

All of these activities are programmed and carried out with the support of our sponsoring companies. Apart from providing vital financial assistance, our sponsors also help to define the Center’s research projects, ensuring their practical relevance.

The companies in question, to which we reiterate our thanks, are: Aena, A.T. Kearney, Caja Madrid, Fundación Ramón Areces, Grupo Endesa, Telefónica and Unión Fenosa.

VALUING COMPANIES WITH A FIXED BOOK-VALUE LEVERAGE RATIO

Abstract

We develop valuation formulae for a company that maintains a fixed book-value leverage ratio and claim that it is more realistic than to assume, as Miles-Ezzell (1980) do, a fixed market-value leverage ratio. The value of tax shields depends only on the present value of the net increases of debt. The value of tax shields in a world with no leverage cost is the tax rate times the current debt plus the present value of the net increases of debt. We also show that the appropriate discount rates for the equity cash flows and for the expected value of the equity are different.

JEL classification: G12; G31; G32

Keywords: Company valuation, value of tax shields, present value of the net increases of debt, required return to equity
VALUING COMPANIES WITH A FIXED BOOK-VALUE LEVERAGE RATIO

Introduction

The value of tax shields defines the increase in the company’s value as a result of the tax saving obtained by the payment of interest. However, there is no consensus in the existing literature regarding the correct way to compute the value of tax shields. Most authors calculate the value of the tax shield in terms of the appropriate present value of the tax savings due to interest payments on debt. Modigliani-Miller (1963) propose that the tax savings be discounted at the risk-free rate\(^1\), whereas Harris and Pringle (1985) and Ruback (1995, 2002) propose that they be discounted at the cost of capital for the unlevered firm. Miles and Ezzell (1985) suggest that the tax savings be discounted in the first year at the cost of debt and in following years at the cost of capital for the unlevered firm. Reflecting this lack of consensus, Copeland et al. (2000, p. 482) claim that “the finance literature does not provide a clear answer about which discount rate for the tax benefit of interest is theoretically correct.”

We show that the value of tax shields depends only upon the nature of the stochastic process of the net increase of debt. More specifically, we prove that the value of tax shields in a world with no leverage cost is the tax rate times the current debt, plus the tax rate times the value of the future net increases of debt.

We provide an alternative to Modigliani-Miller (1963) and to Miles-Ezzell (1980): we develop valuation formulae for companies that maintain a fixed book-value leverage ratio. The Modigliani-Miller (1963) formula should be used when the company has a preset amount of debt; Miles-Ezzell (1980) should be used only if debt will always be a multiple of the equity market value \((D_t = L \cdot S_t)\).

While two theories assume a constant discount rate for the increases of debt (the risk-free rate in Modigliani-Miller, and the appropriate discount rate for the increases of assets if the company maintains a constant book-value leverage ratio), Miles-Ezzell assume one rate for \(t = 1\) and \(K_u\) for \(t > 1\). The appropriate discount rate for the increase of debt in \(t = 1\) is negative, according to Miles-Ezzell, if the expected growth \((g)\) is smaller than \((K_u - R_F)/(1 + R_F)\).

---

\(^1\) Myers (1974) suggests that it be discounted at the cost of debt \((K_d)\).
Although Miles and Ezzell provide a computationally elegant solution (as shown in Arzac-Glosten, 2005), it is not a realistic one. Furthermore, we have not seen any company that follows such a financing policy. It makes much more sense to characterize the debt policy of a company with expected constant leverage ratio as a fixed book-value leverage ratio than as a fixed market-value leverage ratio because:

1. The amount of debt does not depend on stock market movements,
2. It is easier to follow for unlisted companies, and
3. Managers should prefer it because the value of tax shields is higher.

On top of that, the Miles-Ezzell framework gives results that make questionable economic sense:

1. In many scenarios, the present value of the debt increases is negative.
2. The appropriate discount rate for the expected increase of debt in the next period is very low: -177.6% in the example in this paper.
3. The appropriate discount rate for the expected equity cash flow in the next period is very high: 119% in the example in this paper.
4. In many scenarios, the appropriate discount rate for the expected taxes of the levered firm is no higher than the appropriate discount rate for the expected taxes of the unlevered firm.

The Miles-Ezzell setup is equivalent to assuming that the increase of debt is proportional to the increase of the free cash flow in every period, whereas we argue that the increase of debt is proportional to the free cash flow.

We also show that the appropriate discount rate for the expected equity cash flows is different than the appropriate discount rate for the expected value of the equity. The appropriate discount rate for the expected equity cash flows is not constant in every period. Although the equity value of a growing perpetuity can be computed by discounting the expected value of the equity cash flow with a unique average rate (Ke), the appropriate discount rates for the expected values of the equity cash flows are not constant.

Modigliani-Miller and Miles-Ezzell do not make any assumption about the appropriate discount rate for the increases of the book value of assets, but this assumption is needed to calculate the value of the taxes paid by the levered and the unlevered company.

Although Cooper and Nyborg (2006) disagree, this paper shows that formula (28) \( V_{TS} = D \cdot T \cdot \frac{K_u}{[K_u - g]} \) of Fernández (2004) is valid, but only under the assumption that the increases of debt are as risky as the free cash flows.

The paper is organized as follows. In section 1 we derive the general formula for the value of tax shields. In section 2 we apply this formula to specific situations, including a company that maintains a constant book-value leverage ratio. Section 3 is a numerical example. Section 4 proves that the appropriate discount rate for the expected equity cash flows is different than the appropriate discount rate for the expected value of the equity. In sections 5, 6, 7 and 8 we calculate the appropriate discount rates for, respectively, the tax shields, the increases of debt, the value of debt and the value of tax shields. In section 9 we calculate the present value of taxes for the levered and the unlevered firm. Section 10
presents the appropriate discount rates for capital gains. Section 11 discusses the influence of growth on the risk of the cash flows. Section 12 concludes. Table 1 is a map to locate the different formulae in the paper. In the Appendix we derive additional formulae for the three theories discussed in this paper applied to growing perpetuities.

1. General expression of the value of tax shields

The value of the debt today ($D_0$) is the value today of the future stream of interest minus the value today of the future stream of the increases of debt ($\Delta D_t$):

$$D_0 = \sum_{t=1}^{\infty} E[M_t \cdot \text{Interest}_t] - \sum_{t=1}^{\infty} E[M_t \cdot \Delta D_t]$$  

(1)

As the value of tax shields is the value of the interest times the tax rate,

$$VTS_0 = T \sum_{t=1}^{\infty} E[M_t \cdot \text{Interest}_t] = T \cdot D_0 + T \sum_{t=1}^{\infty} E[M_t \cdot \Delta D_t]$$  

(2)

Equation (2), valid for perpetuities and for companies with any pattern of growth, shows that the value of tax shields depends only upon the nature of the stochastic process of the net increase of debt. The problem of equation (2) is how to calculate the value today of the increases of debt, which depends on the financing strategy.

2. Value of tax shields and value of the increases of debt in specific situations

We apply the result in (2) to specific situations and show how this formula is consistent with previous formulae under restrictive scenarios.

The value today of the levered company ($V_{L0}$) is equal to the value of debt ($D_0$) plus that of the equity ($S_0$). It is also equal to the value of the unlevered company ($Vu_0$) plus the value of tax shields due to interest payments ($VTS_0$):

$$V_{L0} = S_0 + D_0 = Vu_0 + VTS_0$$  

(3)

2.1. Debt is proportional to the Equity book value

If $D_t = K \cdot Ebv_t$, where $Ebv$ is the book value of equity, then $\Delta D_t = K \cdot \Delta Ebv_t$. The increase of the book value of equity is equal to the profit after tax (PAT) minus the equity cash flow (ECF). The relationship between the profit after tax of the levered company ($PAT_L$) and the equity cash flow (ECF) is:

$$\sum_{t=1}^{\infty} FCF_t \cdot ME_{Vu}$$  

According to our notation, $Vu_0 = \sum_{t=1}^{\infty} E[M_t \cdot FCF_t]$ and $S_0 = \sum_{t=1}^{\infty} E[M_t \cdot ECF_t]$ where FCF$_t$ is the free cash flow of period $t$, and ECF$_t$ is the equity cash flow of period $t$. 
\[ ECF_t = PAT_{Lt} - \Delta A_t + \Delta D_t \]  

(4)

where \( \Delta A_t \) = Increase of net assets in period \( t \) (Increase of Working Capital Requirements plus Increase of Net Fixed Assets), and \( \Delta D_t = D_t - D_{t-1} \) = Increase of Debt in period \( t \).

Similarly, the relationship between the profit after tax of the unlevered company (PATu) and the free cash flow (FCF) is:

\[ FCF_t = PAT_{u_t} - \Delta A_t \]  

(5)

According to equation (4), as \( \Delta Ebv_t = \Delta D_t / K \),

\[ \Delta Ebv_t = PAT_{Lt} - ECF_t = \Delta A_t - \Delta D_t = \Delta D_t / K \]  

(6)

In this situation, the increase of debt is proportional to the increases of net assets, and the risk of the increases of debt is equal to the risk of the increases of assets:

\[ \Delta D_t = \Delta A_t \cdot K / (1+ K) \]  

(7)

The value today of the increases of debt is:

\[ E_0[M_{0,t} \cdot \Delta D_t] = \left( \frac{K}{1+ K} \right) E_0[M_{0,t} \cdot \Delta A_t] \]  

(8)

We will assume that the increase of net assets follows the stochastic process defined by \( \Delta A_{t+1} = \Delta A_t (1+g)(1+\phi_{t+1}) \). \( \phi_{t+1} \) is a random variable with expected value equal to zero, but with a value today smaller than zero:

\[ E_t[M_{t,t+1} \phi_{t+1}] = - \frac{f}{1+R_F} \]  

(9)

Then, in the case of a growing perpetuity:

\[ E_0[M_{0,t} \cdot \Delta D_t] = \Delta A_0 \left( \frac{K}{1+ K} \right) \frac{(1+g)^t (1-f)^t}{(1+R_F)^t} \]  

(10)

If we say \( 1+\alpha = (1+R_F) / (1-f) \), then

\[ E_0[M_{0,t} \cdot \Delta D_t] = \Delta D_0 \left( \frac{(1+g)^t}{(1+\alpha)^t} \right) \]  

(11)
\( \alpha \) is the appropriate discount rate for the expected increases of the book value of assets\(^3\) and, in this case, the appropriate discount rate for the expected increases of debt. \( \sum E[M_t \Delta D_t] \) is the sum of a geometric progression with growth rate \( = (1+g)/(1+\alpha) \). Therefore:\(^1\)

\[
\sum_t E[M_t \Delta D_t] = \frac{\Delta D_0 (1+g)}{\alpha - g} = \frac{gD_0}{\alpha - g}
\]  
(12)

Substituting (12) in (2), we get:

\[
VTS_0 = \frac{D_0 \alpha T}{(\alpha - g)}
\]  
(13)

As we show in section 5, equation (13) is not the present value of \( D_0 \alpha T \) discounted at \( \alpha \), but the sum of the present values of the expected tax shields (\( D_{t-1} T R_F \)) discounted at different rates in each period.

2.2. Debt is proportional to the Equity book value and the increase of assets is proportional to the free cash flow

If the increase of assets (\( \Delta A_t \)) is proportional to the free cash flow (\( FCF_t \)), \( \alpha = Ku \) and equation (12) is:

\[
\sum_t E[M_t \Delta D_t] = \frac{gD_0}{Ku - g}
\]  
(14)

Substituting (14) in (2), we get:

\[
VTS_0 = \frac{D_0 Ku T}{(Ku - g)}
\]  
(15)

As we assume that the increases of debt and assets are as risky as the free cash flows (\( \alpha = Ku \)), the correct discount rate for the expected increases of debt is \( Ku \), the required return to the unlevered company. (15) is equal to equation (28) in Fernández (2004).\(^4\) Cooper and Nyborg (2006) affirm that equation (15) violates value-additivity. It does not because equation (3) holds.

2.3. The company has a preset amount of debt

In this situation, \( \Delta D_t \) is known with certainty today and Modigliani-Miller (1963) applies: the appropriate discount rate for the \( \Delta D_t \) is \( R_F \), the risk-free rate.

\[
E_0[M_{0,t} \Delta D_t] = \Delta D_0 \frac{(1+g)^t}{(1 + R_F)^t}
\]  
(16)

\(^3\) \( A_t \) is the book value of assets, not the value of the assets, which is the value of the unlevered equity (\( Vu \)).

\(^4\) Fernández (2004) wrongly considered as being zero the present value of a variable with expected value equal to zero. And he neglected to include in equations (5) to (14) terms with expected value equal to zero. Due to these errors, Equations (5) to (17), Tables 3 and 4, and Figure 1 of Fernández (2004) are correct only if \( PV0[\Delta At] = PV0[\Delta Dt] = 0 \).
Equation (16) is the sum of a geometric progression with growth rate \((1+g)/(1+R_F)\). Then:

\[
\sum_{t=1}^{\infty} E[M_t \Delta D_t] = \frac{gD_0}{R_F - g} \tag{17}
\]

Substituting (17) in (2), we get:

\[
VTS_0 = \frac{D_0R_FT}{(R_F - g)} \tag{18}
\]

Modigliani-Miller may be viewed as just one extreme case of section 2.1, in which \(\alpha = R_F\). Fieten et al. (2005) argue that the Modigliani-Miller formula may be applied to all situations. However, it is valid only when the company has a preset amount of debt.

2.4. Debt is proportional to the Equity market value

This is the assumption made by Miles and Ezzell (1980) and Arzac and Glosten (2005). If \(D_t = L \cdot S_t\), the value today of the increase of debt in period 1, if the debt grows at a constant rate \(g\), is:

\[
E_0[M_{0,1} \Delta D_t] = \frac{D_0(1+g)}{1+Ku} - \frac{D_0}{1+R_F} \tag{19}
\]

We prove in the Appendix (equation A.14) that:

\[
\sum_{t=1}^{\infty} E[M_t \Delta D_t] = \frac{D_0}{Ku - g} \left( g - \frac{Ku - R_F}{1+R_F} \right) \tag{20}
\]

Substituting (20) in (2), we get the well known Miles-Ezzell formula:

\[
VTS_0 = \frac{D_0R_FT}{(Ku - g)(1 + R_F)} \tag{21}
\]

We claim that it makes more sense to characterize the debt policy of a growing company with expected constant leverage ratio as a fixed book-value leverage ratio instead of as a fixed market-value leverage ratio because:

1. the debt does not depend on the movements of the stock market,

2. it is easier to follow for unlisted companies, and

3. managers should prefer it because the value of tax shields is higher: (21) is smaller than (15) and smaller than (13).
The Miles-Ezzell setup works as if the company pays all the debt \((D_{t-1})\) at the end of every period \(t\) and simultaneously raises all new debt \(D_t\). The risk of raising the new debt is equal to the risk of the free cash flow and, hence, the appropriate discount rate for the expected value of the new debt (the whole debt, not just the increase of debt) is \(K_u\). The increases of debt are proportional to the increases of the free cash flows.

To assume \(D_t = L \cdot S_t\) is not a good description of the debt policy of any company because if a company has only two possible states of nature in the following period, it is clear that under the worst state (low share price) the leveraged company will have to raise new equity and repay debt, and this is not the moment companies prefer to raise equity. Under the good state, the company will have to take a lot of debt and pay big dividends.

The Miles-Ezzell setup is equivalent to assuming that the increase of debt is proportional to the increase of the free cash flow in every period, whereas in section 2.2 the increase of debt is proportional to the free cash flow.

Table 1 is a map of the formulae in this paper. Table 2 summarizes the implications of several approaches for the value of tax shields and for the value of the future increases of debt.

### 3. A numerical example

Table 3 contains the main valuation results for a constant growing company. It is interesting to note that according to Miles-Ezzell, the present value of the increases of debt is negative.

Table 4 contains the value of the tax shields (VTS) according to the different theories as a function of \(g\) and \(\alpha\). The VTS grows dramatically when \(g\) increases and decreases with \(\alpha\). It may be seen that Modigliani-Miller is equivalent to a constant book-value leverage ratio \((D_t = L \cdot Ebv_t)\), when \(\alpha = R_F = 4\%\). The VTS according to M-M is infinite when \(g > R_F\).

### 4. Appropriate discount rates for the expected equity cash flows and for the expected value of the equity

The value of equity today \((S_0)\) is equal to the present value of the equity cash flow in period 1 \((ECF_1)\) plus the present value of the equity in period 1 \((S_1)\). For perpetuities with a constant growth rate \((g)\):

\[
S_0 = \frac{ECF_0(1+g) + S_0(1+g)}{(1 + Ke_1)} + \frac{S_0(1+g)}{(1 + KS_1)}
\]

(22)

\(Ke_1\) is the appropriate discount rate for the expected equity cash flow in period 1 and \(KS_1\) is the appropriate discount rate for the expected value of the equity in period 1. We will see that both rates are different under all assumptions. The present value of the equity value at \(t = 1\) is

\[
\frac{S_0(1+g)}{(1 + KS_1)} = S_0 - \frac{ECF_0(1+g)}{(1 + Ke_1)}
\]

(23)
The general expression for the present value at t=0 of the equity value at t = t is:

$$S_0 (1 + g)^t = \frac{ECF_0 (1 + g)}{(1 + K_{e1})} - \frac{ECF_{t}(1 + g)^t}{(1 + K_{e1})}$$

To calculate the present value of the equity, we need to calculate the present value of the equity cash flows. The relationship between expected values at t=1 of the free cash flow (FCF), the equity cash flow and the debt cash flow is:

$$CF_0 (1 + g) = FCF_0 (1 + g) - D_0 R_F (1 - T) + g D_0$$  \hspace{1cm} (24)

Ke is the average appropriate discount rate for the expected equity cash flows, such that $$S_0 = \frac{ECF_0 (1 + g)}{(Ke - g)}$$. Ku is the appropriate discount rate for the expected free cash flows, such that $$Vu_0 = \frac{FCF_0 (1 + g)}{(Ku - g)}$$. Equation (24) is equivalent to:

$$S_0 (Ke - g) = Vu_0 (Ku - g) - D_0 (R_F - g) + D_0 R_F T$$  \hspace{1cm} (25)

As, according to equation (3), $$S_0 = Vu_0 - D_0 + VTS_0$$, we may rewrite (25) as:

$$S_0 Ke = Vu_0 Ku - D_0 R_F + VTS_0 g + D_0 R_F T$$  \hspace{1cm} (26)

And the general equation for Ke is:

$$Ke = Ku + \frac{D_0}{S_0} [Ku - R_F (1 - T)] - \frac{VTS_0}{S_0} (Ku - g)$$  \hspace{1cm} (27)

This expression is the average Ke: it is not the required return to the equity cash flows (Ke) for all periods.

4.1. Debt is proportional to the Equity market value

According to Miles and Ezzell (1980) and Arzac and Glosten (2005), substituting (21) in (27), we get:

$$Ke = Ku + \frac{D_0}{S_0} (Ku - R_F) \frac{(1 + R_F - R_F T)}{(1 + R_F)}$$  \hspace{1cm} (28)

If $$D_t = L \cdot S_t$$, the appropriate discount rate for $$S_t (K_S)$$ is also equal to the required return to the debt ($$K_D$$). We prove in the Appendix (equation A.10) that the appropriate discount rate for $$Vu_t$$ is Ku. As according to (21) the VTS is proportional to D, following equation (3), $$D_t$$, $$S_t$$, $$Vu_t$$ and VTS have the same risk, and the appropriate discount rate for all of them is Ku. Therefore, the value of the equity value today is, according to equation (22):

$$S_0 = \frac{ECF_0 (1 + g)}{1 + Ke_t} + \frac{S_0 (1 + g)}{1 + Ku}$$  \hspace{1cm} (29)
The appropriate discount rate for the expected equity cash flow in period 1 (Ke₁) is:

\[
1 + Ke₁ = \frac{ECF₀(1+g)(1+Ku)}{S₀(Ku-g)} = (1+Ku)\frac{(Ke-g)}{(Ku-g)}
\]  

(30)

The value of the equity today is also:

\[
S₀ = \frac{ECF₀(1+g)}{(1+Ke₁)} + \frac{ECF₀(1+g)^2}{(1+Ke₁)(1+Ke₂)} + \frac{S₀(1+g)^2}{(1+Ku)^2}
\]

(31)

Substituting (30) in (31), it is clear that Ke₂ = Ku. Following the same procedure, it may be shown that for t >1, Ke_t = Ku. In the example in Table 3, Keₐ =16.07%, Ke₁=119.03% and KS₁= Ku = 9%.

4.2. Debt is proportional to the Equity book value

Substituting (13) in (27), we get:

\[
Ke = Ku + \frac{D₀}{S₀}\left[ Ku - R_F(1-T) - \alpha T(Ku-g) \right]
\]

(32)

Calculating the expected value of equation (24) at t=0:

\[
\frac{(1+g)ECF₀}{(1+Ke₁)} - \frac{(1+g)FCF₀}{(1+Ku)} - \frac{D₀R_F(1-T)}{(1+R_F)} + \frac{gD₀}{(1+\alpha)}
\]

(33)

As (1+g)ECF₀=S₀ (Ke-g) and (1+g)FCF₀=Vu₀ (Ku-g), the appropriate discount rate for the expected equity cash flow in period 1 is:

\[
(1 + Ke₁) = \frac{S₀(Ke-g)}{Vu₀(1+Ku) + D₀\left\{ \frac{g}{(1+\alpha)} - \frac{R_F(1-T)}{(1+R_F)} \right\}}
\]

(34)

And substituting (34) in (23):

\[
\frac{S₀(1+g)}{(1+KS₁)} = S₀ - Vu₀(1+g) - D₀\left\{ \frac{g}{(1+\alpha)} - \frac{R_F(1-T)}{(1+R_F)} \right\}
\]

(35)

In the Appendix we find the present value of the equity value in t (A.27) and the discount rate for the expected equity cash flow in t (A.30):
In the example in Table 3, if $\alpha=7\%$, $Ke=11.63\%$, $Ke_1=9.98\%$ and $Ks_1=11.80\%$. In the example $PV_0[S_t]<0$ for $t>25$ and $PV_0[ECF_t]<0$ for $t>46$. $PV_0[S_t]<0$ only means that $PV_0[Vu] + PV_0[VTSt]$. $PV_0[ECF_t]<0$ only means that $PV_0[Dt-1 R_F(1-T)] > PV_0[FCF_t] + PV_0[\Delta Dt]$. 

### 4.3. Debt is proportional to the Equity book value and the increase of assets is proportional to the free cash flow

In this situation, as the increases of assets are proportional to the free cash flows ($\Delta A_{t+1} = Z \cdot FCF_t$), $\alpha= Ku$, and equation (32) is:

$$Ke = Ku + \frac{D_0}{S_0} (Ku - R_F)(1-T)$$

(38)

If $\alpha = Ku$, as $Vu_0 = S_0 + D_0 - VTS_0$, equations (34) and (35) are:

$$V_{Uo}(1+g)\Delta t = \frac{(Ke - g)(1+R_F)(1+Ku)}{(Ku-g)(1+R_F)+(Ke-Ku)}$$

(39)

And equations (36) and (37) are:

$$PV_0[S_t] = \frac{S_0(Ke-g)}{(1+Ku)^{\Delta t}} + D_0(1-T)(Ku-R_F)\left[\frac{(1+g)^{\Delta t}}{(Ku-R_F)^{\Delta t}} - \frac{1}{(1+R_F)^{\Delta t}}\right]$$

(42)
When \( t \) tends to infinity, \( K_{et} = K_{St} = (1+g)(1+R_F)-1 \) if \((1+g)(1+R_F) < (1+K_u)\) and \( K_{et} = K_{St} = K_u \) if \((1+g)(1+R_F) > (1+K_u)\).

In the example in Table 3, if \( \alpha = K_u = 9\% \), \( K_e = 12.09\% \), \( K_{et1} = 10.30\% \) and \( K_{S1} = 12.27\% \). In the example, \( PV_0[R_0] < 0 \) for \( t > 24 \) and \( PV_0[ECF_t] < 0 \) for \( t > 44 \).

### 4.4. The company has a preset amount of debt

Modigliani-Miller may be viewed as just one extreme case of section 4.2, in which \( \alpha = R_F \). Substituting (18) in (27) (or substituting \( \alpha \) by \( R_F \) in (32)), we get:

\[
K_e = K_u + \frac{D_0}{S_0} \left[ \frac{K_u - R_F - R_T}{R_F - g} \right] \quad (43)
\]

But this expression is the average \( K_e \). It is not the required return to equity (\( K_{et} \)) for all the periods. Substituting \( \alpha \) by \( R_F \) in (34) and (35):

\[
(1 + K_{et}) = \frac{(K_e - g)(1 + K_u)(1 + R_F)}{(K_u - g)(1 + R_F) + (K_e - K_u)(1 + g)} \quad (44)
\]

\[
S_0(1+g) = S_0 - V\alpha_0(1+K_u) + D_0 \frac{R_F(1-T) - g}{(1+R_F)} = \frac{S_0(1+g)[1+R_F - Ke + Ku]}{(1+R_F)(1+K_u)} \quad (45)
\]

In this situation, the appropriate discount rate for the expected value of tax shields (VTS) and for the expected debt is the risk-free rate.

Substituting \( \alpha \) by \( R_F \) in (36) and (37), and taking into account that \( V\alpha_0 = S_0 + D_0 - VTS_0 \), we get:

\[
(1 + K_{et}) = \frac{S_0(K_e - g)}{V\alpha_0(1+K_u)} - D_0 \frac{R_F(1-T) - g}{(1+R_F)} \quad (46)
\]

\[
E_0[M_{0t}, S_t] = V\alpha_0 \left[ \frac{1+g}{1+K_u} \right] - D_0 \frac{R_F(1-T) - g}{(1+R_F)} \quad (47)
\]

In the appendix (A.33) we show that

\[
\prod (1 + K_{et}) = \frac{S_0(1+R_F)^{t}(1+K_u)^{t}}{(S_0 - V\alpha_0)(1+K_u)^{t} + V\alpha_0(1+R_F)^{t}} \quad (48)
\]

Comparing (46) and (47) it is clear that the appropriate discount rate for the equity cash flow is different that the appropriate discount rate for the expected value of the equity.
From (47) we see that the present value of the equity is negative if

\[ t > \log \left( \frac{V_{u0}(R_F - g)}{D_0[R_F(1-T) - g]} \right) / \log \left( \frac{1 + Ku}{1 + R_F} \right) \]

When \( t \) tends to infinity, \( Ke_t = K_{S1} = R_F \)

In the example in Table 3, \( Ke = 9.80\% \), \( Ke_1 = 9.21\% \) and \( K_{S1} = 9.84\% \). \( PV_0[S_t] < 0 \) for \( t > 42 \) and \( PV_0[ECF_t] < 0 \) for \( t > 68 \).

Although the equity value of a growing perpetuity can be computed by discounting the expected value of the equity cash flow with a unique average rate \( Ke \), the appropriate discount rates for the expected values of the equity cash flows are not constant. Table 5 presents the appropriate discount rates for the expected values of the equity cash flows of our example. According to Miles-Ezzell, \( Ke_t \) is 119.03\% for \( t = 1 \) and 9\% for the rest of the periods. According to Modigliani-Miller, \( Ke < Ku \) if \( g > R_F(1-T) \).

For all cases, the expected total return for the shareholder (\( K_{SHAR1} \)) is \( Ke \) for all periods because:

\[
K_{SHAR1} = \frac{gS_0 + ECF_0(1+g)}{S_0} = \frac{gS_0 + S_0(Ke-g)}{S_0} = Ke
\]

5. **Appropriate discount rates for the tax shields (\( K_{TS2} \))**

The tax shield of the next period is known with certainty (\( D_0 \ R_F \ T \)) under all methods and the appropriate discount rate is \( R_F \).

If the company maintains a constant book-value leverage, the appropriate discount rate for the expected increases of debt is \( \alpha \); and the appropriate discount rate for the expected tax shield of \( t = 2 \) (\( K_{TS2} \)) is such that:

\[
\frac{D_0(1+g)R_F T}{(1 + R_F)(1 + K_{TS2})} = R_F T \left[\frac{D_0}{(1 + R_F)^2} + \frac{gD_0}{(1 + R_F)(1 + \alpha)}\right] \quad (49)
\]

\[
1 + K_{TS2} = \frac{(1 + R_F)(1 + \alpha)(1+g)}{1 + \alpha + g(1 + R_F)} \quad (50)
\]

In the appendix (A.18), we show that the present value of the tax shield in \( t \) is:

\[
PV_0[TS_t] = R_F TD_0 \left[\frac{1}{(1 + R_F)^t} + \frac{g[X^{t-1} - 1]}{(1 + R_F)^t - 1} \left[1 + \alpha \right][X - 1] \right] \quad (51)
\]

We also prove that the appropriate discount rate for the expected tax shield of period \( t \), for \( t > 1 \), is:

\[
(1 + K_{TS_t}) = \frac{PV_0[TS_{t-1}]}{PV_0[TS_t]}(1 + g) = X(1 + \alpha) \frac{(1 + \alpha)(X - 1) + g(1 + R_F)(X^{t-2} - 1)}{(1 + \alpha)(X - 1) + g(1 + R_F)(X^{t-1} - 1)} \quad (52)
\]
In the example in Table 3, if \(\alpha = 7\%\), \(K_{TS2} = 4.057\%\).

When \(t\) tends to infinity, \(K_{TS} = \text{MIN}[\alpha, (1+R_F)(1+g)-1]\)

It is also easy to calculate that, using (51), \(V_{TS0} = \sum_{t=0}^{\infty} PV_{0}[TS_t] = \frac{D_0 T\alpha}{\alpha - g}\)

According to Miles-Ezzell, the appropriate discount rate for the expected tax shields is \(R_F\) for \(t = 1\) and \(K_u\) for \(t > 1\).

According to Modigliani-Miller, as the debt in any period is known today, the appropriate discount rate for the expected tax shields of any period \((K_{TS})\) is \(R_F\).

6. Appropriate discount rates for the increases of debt \((K_{AD1})\)

If the company maintains a constant book-value leverage, the appropriate discount rate for the expected increases of debt \((K_{AD0})\) is \(\alpha\). According to Modigliani-Miller, as the debt in any period is known today, the appropriate discount rate for the expected increases of debt is \(R_F\). According to Miles-Ezzell, the equivalent discount rate for the expected increase of debt in period 1 \((K_{AD1})\) is such that:

\[
E_0[\Delta D_1] = \frac{g D_0}{1 + K_{AD1}} = \frac{D_0(1+g)}{1 + K_u} = \frac{D_0}{1 + R_F}
\]

(53)

Some algebra permits to express \(1 + K_{AD1} = \frac{g(1+K_u)(1+R_F)}{g(1+R_F)+R_F-K_u}\)

(54)

In our example, \(K_{AD1} = -177.6\%\).

For \(t=2\): \(E_0[M_{0,2}\Delta D_2] = \frac{D_0(1+g)}{(1+K_u)} \left( \frac{(1+g)}{(1+K_u)} - \frac{1}{(1+R_F)} \right) = \frac{g D_0 (1+g)}{(1+K_{AD1})(1+K_{AD2})}\)

After equation (53) it is obvious that \(K_{AD2} = K_u\). Repeating this exercise, we find that \(K_{ADt} = K_u\). Under Miles-Ezzell the appropriate discount rate for \(V_{Ut}, D_t, VTS_t\) and \(V_{Ut}\) is \(K_u\), and as all of them are multiples of the free cash flow, also \(\Delta D_t\) is a multiple of the \(\Delta FCF_t\): \(\Delta D_t = [D_0 / FCF_0]\Delta FCF_0\).

Table 6 contains the value today of the increases of debt in different periods and the sum of all of them. According to Miles-Ezzell the value today of the increases of debt in

\[\text{\footnotesize 5} \text{ This result may be obtained also calculating (52) when } \alpha = R_F\]

\[\text{\footnotesize 6} \text{ If } g=0, \text{ then } K_{AD1} \text{ according to (54) is } -100\%, \text{ which does not make any economic sense. In this situation the expected value of the increase of debt is } 0, \text{ but } E_0[M_{0,1}\Delta D_1] = \frac{D_0}{1+K_u} - \frac{D_0}{1+R_F}\]
every period is negative. It is interesting to note that while two theories assume a constant
discount rate for the increases of debt (Modigliani-Miller assume \( R_F \) and constant book
value leverage assumes \( \alpha \)), Miles-Ezzell assume one rate for \( t = 1 \) and \( Ku \) for \( t > 1 \). The
appropriate discount rate for the increase of debt in \( t = 1 \) is, according to Miles-Ezzell,
equation (53), which is negative if \( g < (Ku - R_F)/(1 + R_F) \).

7. Appropriate discount rates for the value of debt (\( K_{Dt} \))

The expected value of debt at \( t=1 \) (\( D_0(1+g) \)) and the value of the debt today (\( D_0 \))
must accomplish equation (55):

\[
D_0 = \frac{D_0}{1 + R_F} \left( 1 + \frac{g D_0}{1 + K_{\Delta D1}} \right) + \frac{D_0(1 + g)}{1 + K_{D1}}
\]

Substituting the expressions for \( K_{D2} \) (appropriate discount rate for the expected
increases of debt) from the previous section, we find that:

a) according to Miles-Ezzel, \( K_{D1} = Ku \)

b) according to Modigliani-Miller, \( K_{D1} = R_F \)

c) with constant book-value leverage, \( 1 + K_{D1} = \frac{(1 + g)(1 + \alpha)(1 + R_F)}{1 + \alpha + g(1 + R_F)} \) (56)

As \( K_{Dt} = K_{TS+1} \) we prove in the appendix (A.20) that:

\[
(1 + K_{D1})...(1 + K_{Dt}) = \frac{(1 + g)^t(1 + R_F)^t}{1 + \frac{g(1 + R_F)}{1 + \alpha}(X - 1)}
\]

(57)

if \( \alpha = R_F \) \( (1 + K_{D1})...(1 + K_{Dt}) = (1 + R_F)^t \). For \( t = 1 \), (57) is equal to (56)

In the example in Table 3, \( K_{D1} \) and \( K_{D2} \) are 4.06% and 4.11%. When tends to
infinity, \( 1 + K_{Dt} = (1 + g)(1 + R_F) \) if \( X < 1 \), and \( 1 + K_{Dt} = (1 + \alpha) \) if \( X > 1 \).

d) with constant book-value leverage and \( \Delta D_t = M FC_t \):

\[
1 + K_{D1} = \frac{(1 + g)(1 + Ku)(1 + R_F)}{1 + Ku + g(1 + R_F)}
\]

In the example in Table 3, \( K_{D1} \) and \( K_{D2} \) are 4.09% and 4.18%.
8. Appropriate discount rates for the value of tax shields ($K_{VTS1}$)

The expected value of the tax shield at $t=1$ ($VTS_0(1+g)$) and the value of tax shields today ($VTS_0$) must accomplish equation (58):

$$VTS_0 = \frac{D_0 R_F T}{1+R_F} + \frac{VTS_0(1+g)}{1+K_{VTS1}}$$  (58)

Substituting the expressions for the value of the tax shields (equations (13), (15), (18) and (21)), we find that:

a) according to Miles-Ezzel, $K_{VTS1} = K_u$

b) according to Modigliani-Miller, $K_{VTS1} = R_F$

c) with constant book-value leverage, $1 + K_{VTS1} = \frac{\alpha(1+R_F)(1+g)}{\alpha + gR_F}$  (59)

In the example in Table 3, $K_{VTS1}$ and $K_{VTS2}$ are 4.88% and 4.91%.

d) with constant book-value leverage and $\Delta D_t = MFCF_t$:

$$1 + K_{VTS1} = \frac{K_u(1+R_F)(1+g)}{K_u + gR_F}$$

In the example in Table 3, $K_{VTS1}$ and $K_{VTS2}$ are 5.15% and 5.18%.

With constant book-value leverage ($D_t = K Ebvt$), $K_{D1}$ and $K_{VTS1}$ are not equal:

$$K_{VTS1} - K_{TS1} = \frac{g(1+R_F)(1+g)}{K_u + gR_F}$$

In the case of constant book-value leverage, we prove in the Appendix (A.22) that:

$$PV_0[VTS_1] = \frac{TD_0}{(1+R_F)^t} \left[ 1 + \frac{gR_F X^t}{X - 1} \right]$$  (60)

From (60), we get:

$$(1+K_{VTS1})...(1+K_{VTS1}) = \frac{\alpha(X-1)(1+R_F)^t(1+g)^t}{gR_F X^t - \frac{(\alpha - R_F)(\alpha - g)}{(1+\alpha)}}$$  (61)

9. Value today of the expected taxes

We also derive the appropriate discount rates for the expected values of the taxes. If we assume that the appropriate discount rate for the increases of assets is $K_u$, then the appropriate discount rate for the expected value of the taxes of the unlevered company is also $K_u$. But the appropriate discount rate for the expected value of the taxes of the levered
company (K_{TAXL}) is different according to the three theories. According to Modigliani-Miller and Fernández, the taxes of the levered company are riskier than the taxes of the unlevered company. According to Miles-Ezzell, however, both taxes are equally risky for \( t > 1 \).

If leverage costs do not exist, that is, if the expected free cash flows are independent of leverage,\(^7\) the value of tax shields (VTS) may be stated as follows

\[
VTS_0 = G_{U0} - G_{L0}
\]

where \( G_{U0} \) is the present value of the taxes paid by the unlevered company and \( G_{L0} \) is the present value of the taxes paid by the levered company.

Taking into consideration equations (4) and (5), the taxes paid every year by the unlevered company (TaxesU) and by the levered company (TaxesL) are:

\[
\text{Taxes}_{Ut} = \left[ \frac{T}{1-T} \right] \text{PAT}_t = \left[ \frac{T}{1-T} \right] (\text{FCF}_t + \Delta A_t)
\]

\[
\text{Taxes}_{Lt} = \left[ \frac{T}{1-T} \right] (\text{ECF}_t + \Delta A_t - \Delta D_t)
\]

The present values at \( t=0 \) of equations (63) and (64) are:

\[
G_{U0} = \left( \frac{T}{1-T} \right) \left[ V_{U0} + \sum_{i=1}^{\infty} E[M_t \cdot \Delta A_t] \right]
\]

\[
G_{L0} = \left( \frac{T}{1-T} \right) \left[ S_0 + \sum_{i=1}^{\infty} E[M_t \cdot \Delta A_t] - \sum_{i=1}^{\infty} E[M_t \cdot \Delta D_t] \right]
\]

The value of tax shields is the difference between \( G_{U} \) (65) and \( G_{L} \) (66).

In section 2.1 we defined \( \alpha \) as the appropriate discount rate for the expected increases of the book value of assets. Modigliani-Miller and Miles-Ezzell do not make any assumption about the appropriate discount rate for the increases of the book value of assets, but this assumption is needed to calculate the value of the taxes paid by the levered and the unlevered company. The appropriate discount rate for the expected taxes of the unlevered company (\( K_{TAXU1} \)) is such that:

\[
E_0[\text{Taxes}_{U1}] = \left[ \frac{T}{1-T} \right] \left[ (1+g) \text{FCF}_0 + gA_0 \right] \frac{(1+\alpha)}{(1+\alpha)}
\]

As \( E[\text{Taxes}_{U1}] = [T/(1-T)] \left[ (1+g) \text{FCF}_0 + gA_0 \right] \), we can calculate \( K_{TAXU1} \).

\[
(1 + K_{TAXU1}) = \frac{(1+g) \text{FCF}_0 + gA_0}{(1+\alpha)(1+\alpha) + gA_0(1+\alpha)}
\]

\(^7\) It the risk of the increase of assets is smaller than the risk of the free cash flows, then Miles-Ezzell provides a surprising result: the taxes of the levered company are less risky than the taxes of the unlevered company.

\(^8\) When leverage costs do exist, the total value of the levered company is lower than the total value of the unlevered company. A world with leverage cost is characterized by the following relation:

\[
Vu + Gu = S + D + GL + \text{Leverage Cost} > S + D + GL
\]

Leverage cost is the reduction in the company’s value due to the use of debt.
If \( \alpha = Ku \), then \( K_{TAXU} = Ku \).

The appropriate discount rate for the expected taxes of the levered company is:

\[
E_0[Taxes_{L1}] = \frac{T}{1-T} \left[ \frac{(1+g)FCF_0 + gA_0 - D_0R_F(1-T)}{(1+Ku)(1+\alpha)} \right]
\]

As \( E[Taxes_{L1}] = \frac{[T/(1-T)] [FCF_0(1+g) + gA_0 - D_0R_F(1-T)]}{1+K_{TAXL1}} \)

\[
1+K_{TAXL1} = \frac{(1+g)FCF_0 + gA_0 - D_0R_F(1-T)}{(1+Ku)(1+\alpha)} - \frac{D_0R_F(1-T)}{(1+R_F)}
\]

For \( t > 1 \), (for example, for \( t=2 \)), the present value is:

\[
PV_0[Taxes_{L2}] = \frac{E_0[Taxes_{L1}](1+g)}{(1+K_{TAXL1})(1+K_{TAXL2})}
\]

It is obvious that, according to Miles-Ezzell, \( K_{TAXL2} = Ku \) if \( \alpha = Ku \).

From equation (62) we can calculate the present value of the levered taxes also as:

\[
G_{L0} = Gu_0 - VTS_0 = \frac{T}{1-T} \left[ Vu_0 + \frac{gA_0}{(\alpha - g)} \right] - VTS_0
\]

Although \( K_{TAXU} \) and \( K_{TAXL} \) are not constant, we can calculate \( K_{TAXU} \) and \( K_{TAXL} \) such that \( G_{L0} = Taxes_{L0} (1+g) / (K_{TAXL} - g) \) and \( G_{L0} = Taxes_{L0} (1+g) / (K_{TAXL} - g) \). Some algebra permits to find, for all theories:

\[
K_{TAXU} = \frac{Vu_0(\alpha - g)Ku + gA_0}{Vu_0(\alpha - g) + gA_0}
\]

\[
K_{TAXL} = \frac{g + S_0(Ke - g) + g(A_0 - D_0)}{Vu_0 + \frac{gA_0}{(\alpha - g)} - \frac{VTS_0(1-T)}{T}}
\]

In our example (Table 3), if \( \alpha = 7\% \), \( Gu = 870.48 \), and \( K_{TAXU} = 8.437\% \), but \( K_{TAXU} \) is 8.556\% and tends to 7\% when \( t \) tends to infinity. If \( \alpha = 9\% = Ku \), \( Gu = 946.67 \), and \( K_{TAXU} = K_{TAXU} \) is 9\%. According to Miles-Ezzell, \( K_{TAXL} < K_{TAXU} \).

Table 7 presents the appropriate discount rates for the expected values of the taxes in the initial periods for our example and their average. According to Miles-Ezzell, if \( \alpha = Ku = 9\% \), \( K_{TAXL} \) is 10.19\% for \( t = 1 \) and 9\% (equal to \( K_{TAXU} \)) for the rest of the periods.
According to Miles-Ezzell, if $\alpha = 7\%$, $K_{TAXL1}$ is 9.64% and $K_{TAXL2}$ is 8.44% (smaller than $K_{TAXU2}$). According to the other theories, $K_{TAXLt}$ is higher than $K_{U}$ (9%) and grows with $t$.

10. Appropriate discount rate for capital gains

In the Appendix, we deduct the appropriate discount rate for the expected capital gains in formulae (A.37) to (A.41). It may be seen that for our example the appropriate discount rate for the capital gains in the first periods are negative according to all theories. This result contradicts Cooper and Nyborg (2006), who affirm that "since capital gains are known with certainty, the appropriate discount rate for them is the risk free rate".

11. Is $K_{U}$ independent of growth?

Up to now we have assumed that $K_{U}$ is constant, independent of growth. From equation (6) we know that $FCF_{t} = PAT_{u} - \Delta A_{t}$.

If we consider that the risk of the unlevered profit after tax (PAT$_{u}$) is independent of growth, and that $K_{PATu}$ is the required return to the expected PAT$_{u}$, the present value of equation (6) is:

$$V _{u0} = \frac{(1+g)FCF_{0}}{(K_{u} - g)} - \frac{(1+g)PAT_{u0}}{(K_{PATu} - g)} \frac{gA_{0}}{(\alpha - g)}$$

$$K_{u} = g + \frac{(1+g)FCF_{0}}{(1+g)PAT_{u0} - gA_{0}} \frac{gA_{0}}{(K_{PATu} - g) - (\alpha - g)}$$

Table 8 contains the required return to the free cash flows ($K_{u}$) as a function of (required return to the increase of assets)and $g$ (expected growth). It may be seen that $K_{u}$ is increasing in $g$ if $\alpha < K_{PATu}$, and decreasing in $g$ if $\alpha > K_{PATu}$

12. Conclusions

The value of tax shields depends only upon the nature of the stochastic process of the net increase of debt. More specifically, the value of tax shields in a world with no leverage cost is the tax rate times the current debt, plus the tax rate times the value today of the net increases of debt. This expression is equivalent to the difference between the present values of two different cash flows, each with its own risk: the value today of taxes for the unlevered company and the value today of taxes for the levered company. The critical parameter for calculating the value of tax shields is the value today of the net increases of debt.

---

9 This result contradicts Cooper and Nyborg (2006), who maintain that “$K_{u}$ is decreasing in $g$".
When the debt level is fixed, Modigliani-Miller (1963) applies, and the tax shields should be discounted at the required return to debt. If the leverage ratio (D/E) is fixed at market value, then Miles-Ezzell (1980) applies with the caveats discussed. If the leverage ratio is fixed at book values and the increases of assets are as risky as the free cash flows (the increases of debt are as risky as the free cash flows), then Fernández (2004) applies. We have developed new formulas for the situation in which the leverage ratio is fixed at book values but the increases of assets have a different risk than the free cash flows.

We argue that it is more realistic to assume that a company maintains a fixed book-value leverage ratio than to assume, as Miles-Ezzell (1980) do, that the company maintains a fixed market-value leverage ratio because:

5. The amount of debt does not depend on the movements of the stock market,
6. It is easier to follow for unlisted companies, and
7. Managers should prefer it because the value of tax shields is higher.

On top of that, the Miles-Ezzell framework provides some results that make questionable economic sense:

1. In many scenarios, the present value of the debt increases is negative.
2. The appropriate discount rate for the expected increase of debt in the next period is too high: -177.6% in the example in this paper.
3. The appropriate discount rate for the expected equity cash flow in the next period is too high: 119% in the example in this paper.
4. In many scenarios, the appropriate discount rate for the expected taxes of the levered firm is equal to or lower than the appropriate discount rate for the expected taxes of the unlevered firm.

Appendix 1 General set up and derivation of some valuation formulae

To avoid arguments about the appropriate discount rates, we will use pricing kernels. The price of an asset that pays a random amount \( x_t \) at time \( t \) is the sum of the expectation of the product of \( x_t \) and \( M_t \), the pricing kernel for time \( t \) cash flows:

\[
P_x = \sum_{t=1}^{\infty} E[M_t x_t]
\]

We will assume that

\[
FCF_{t+1} = FCF_t (1 + g)(1 + \epsilon_{t+1})
\]  

\( \epsilon_{t+1} \) is a random variable with expected value equal to zero \( (E_\epsilon[\epsilon_{t+1}] = 0) \), but with a value today smaller than zero:

\[
E_1[M_{t+1} \epsilon_{t+1}] = -\frac{d}{1 + R_F}
\]  

The risk-free rate corresponds to the following equation:

\[
\frac{1}{1 + R_F} = \sum_{t=1}^{\infty} E[M_t] \]  

First, we deduct the value of the unlevered equity. If \( M_{t+1} \) is the one-period pricing kernel at time \( t \) for cash flows at time \( t+1 \),

\[ Vu_t = E_1[M_{t+1} FCF_{t+1}] + E_1[M_{t+1} Vu_{t+1}] \]  

A solution must be \( Vu_t = a\cdot FCF_t \); then:

\[ Vu_t = E_1[M_{t+1} FCF_{t+1}] + E_1[M_{t+1} a FCF_{t+1}] = (1 + a) E_1[M_{t+1} FCF_{t+1}] \]  

According to (A.1):

\[ E_1[M_{t+1} FCF_{t+1}] = E_1[M_{t+1} FCF_t (1 + g)] + E_1[M_{t+1} FCF_t (1 + g) \epsilon_{t+1}] \]  

Using equation (A.6) and defining \( Ku = (R_F + d) / (1 - d) \):

\[ E_1[M_{t+1} FCF_{t+1}] = \frac{FCF_t (1 + g)}{1 + R_F} - \frac{FCF_t (1 + g) d}{1 + R_F} = \frac{FCF_t (1 + g) (1 - d)}{1 + R_F} = \frac{FCF_t (1 + g)}{1 + Ku} \]  

\[ Vu_t = a FCF_t = (1 + a) \frac{FCF_t (1 + g)}{1 + Ku} ; \quad a = \frac{(1 + g)}{Ku - g} \]  

Then:

\[ v_{u_1} = \sum_{t=1}^{\infty} E[M_t \cdot FCF_t] = \frac{(1+g)}{K_u - g} FCF_t \]  

(A.9)

The appropriate discount rate for \( V_{u_t} \) is also \( K_u \) because:

\[
\begin{align*}
V_{u_0} &= \frac{FCF_0(1+g)}{1+K_u} + \frac{V_{u_0}(1+g)}{1+K_u} = \frac{V_{u_0}(K_u-g)}{1+K_u} + \frac{V_{u_0}(1+g)}{1+K_u} = V_{u_0} \\
\end{align*}
\]

(A.10)

If \( D_t = L \cdot S_t \), the appropriate discount rate for the expected value of the unlevered equity (\( V_{u_t} \)), for the expected value of the debt (\( D_t \)), for the expected value of the tax shields (\( V_{TS_t} \)), and for the expected value of the equity (\( S_t \)), is \( K_u \) in all periods.

Using (A.10), the appropriate discount rate for \( \Delta V_{u_1} (K_{\Delta V_{u_1}}) \) is:

\[
\begin{align*}
V_{u_0} &= \frac{V_{u_0}(K_u-g)}{1+K_u} + \frac{V_{u_0}(1+g)}{1+K_u} = \frac{V_{u_0}(K_u-g) + V_{u_0}}{1+R_F} + \frac{gV_{u_0}}{1+K_{\Delta V_{u_1}}} \\
1 + K_{\Delta V_{u_1}} &= \frac{g(1+K_u)(1+R_F)}{g(1+R_F) - (K_u - R_F)} \\
\end{align*}
\]

(A.11)

(A.12)

As \( V_{u_t} = a \cdot FCF_t; K_{\Delta V_{u_1}} = K_{\Delta FCF_1}. \) Looking at (54), \( K_{\Delta V_{u_1}} = K_{\Delta D_t}. \)

For \( t=2, \) as the expected value of \( \Delta V_{u_2} \) is \( gV_{u_0}(1+g) \), the expected value of the difference between \( V_{u_2} \) and \( V_{u_1} \), known in \( t=1 \):

\[
\frac{gV_{u_0}(1+g)}{(1+K_{\Delta V_{u_1}})(1+K_{\Delta V_{u_2}})} = \frac{V_{u_0}(1+g)^2}{(1+K_u)^2} - \frac{V_{u_0}(1+g)}{(1+K_u)(1+R_F)}
\]

It is clear that \( K_{\Delta V_{u_2}} = K_u = K_{\Delta FCF_2}. \) Using the same argument, it may be shown that for \( t>1, K_{\Delta V_{u_1}} = K_u = K_{\Delta FCF_t} \)

**Miles-Ezzell present value of the increases of debt**

Equation (19) is the present value of the expected increase of debt in period 1. The present value of the expected increase of debt in period \( t \) (as \( D_{t-1} \) is known in period \( t-1 \)) is:

\[
E_0[M_{0,t} \cdot \Delta D_t] = \frac{D_0(1+g)^t}{(1+K_u)^t} - \frac{D_0(1+g)^{t-1}}{(1+R_F)(1+K_u)^{t-1}}
\]

(A.13)

The sum of all the present values of the expected increases of debt is a geometric progression with growth rate = \((1+g)/(1+K_u)\). The sum is:
\[
\sum_{t=1}^{\infty} E_0[M_{0,t} \cdot \Delta D_t] = \frac{D_0}{(K_u - g)} \left( g - \frac{K_u - R_F}{1 + R_F} \right)
\]  
(A.14)

**Miles-Ezzell formulae with continuous adjustment of debt**

If debt is adjusted continuously, not only at the end of the period, then the Miles-Ezzell formula (21) changes to

\[
VTS_0 = \int_0^\infty T \rho D_t e^{(\gamma - \kappa)t} dt = \frac{D_0 \rho T}{\kappa - \gamma}
\]  
(A.15)

where \( \rho = \ln(1+R_F) \), \( \gamma = \ln(1+g) \), and \( \kappa = \ln(1+K_u) \).

Perhaps formula (A.15) induces Cooper and Nyborg (2006) and Ruback (1995 and 2002) to use (A.16) as the expression for the value of tax shields when the company maintains a constant market-value leverage ratio (\( D_t = L \cdot S_t \)):

\[
VTS_0 = \frac{D_0 R_F T}{K_u - g}
\]  
(A.16)

But (A.16) is incorrect for discrete time: (21) is the correct formula.

\( D_t = L \cdot E_t \) is absolutely equivalent to \( D_t = M \cdot V_u_t \). In both cases \( \Delta D_t = X \cdot \Delta FCF_t \), where \( X = D_0 / FCF_0 \).

**Derivation of formulas if debt is proportional to the book value of equity**

The present value of the tax shield of period \( t \) is:

\[
\frac{D_0 (1+g)^{t-1} R_F T}{(1+R_F)(1+K_{TS})...(1+K_{TS_t})} = \frac{D_0 R_F T}{(1+R_F)^t} + \frac{gD_0 R_F T}{(1+R_F)^{t-1}(1+\alpha)} + ... + \frac{g^{t-1} D_0 (1+g)^{t-2} R_F T}{(1+R_F)(1+\alpha)^{t-1}}
\]  
(A.17)

\( K_{TS} \) is the appropriate discount rate for the tax shields (TS). (A.17) takes into consideration the fact that the appropriate discount rate for the increases of debt is \( \alpha \). (A.17) is the sum of a geometric progression with a factor \( X = (1+g)(1+R_F)/(1+\alpha) \). The solution is:

\[
PV_0[TS_t] = R_F T D_0 \left[ \frac{1}{(1+R_F)^t} + \frac{g^{t-1} X - 1}{(1+R_F)^{t-1}(1+\alpha)[X - 1]} \right]
\]  
(A.18)

And the appropriate discount rate for the expected tax shield of period \( t \) is:
\[ PV_0[T_{S,t+1}] = \frac{PV_0[T_{S,t-1}]}{(1+g)} = X(1+\alpha) \frac{(1+\alpha)(X-1)+g(1+R_F)(X^{t'-1}-1)}{(1+\alpha)(X-1)+g(1+R_F)(X^{t'-1}-1)} \]  
(A.19)

As \( K_{D,t} = K_{T,t}+1 \) using (A.18), we know that:

\[ PV_0[T_{S,t+1}] = \frac{R_F T D_0 (1+g)^t}{(1+R_F)(1+K_{D,t})...(1+K_{D,t})} = R_F T D_0 \left[ \frac{1}{(1+R_F)^{t+1}} + \frac{g[X^{t'-1}]}{(1+R_F)^{t+1}(1+\alpha)(X-1)} \right] \]

\[ (1+K_{D,t})...(1+K_{D,t}) = \frac{(1+R_F)^t(1+g)^t}{1+(1+R_F)g[X^{t'-1}]} \]

(A.20)

And the present value of the debt in \( t \) is:

\[ PV_0[D_t] = \frac{D_0(1+g)^t}{(1+K_{D,t})...(1+K_{D,t})} = \frac{D_0}{(1+R_F)^t} \left[ 1 + \frac{g(1+R_F)[X^{t'-1}]}{(1+\alpha)(X-1)} \right] \]  
(A.21)

We calculate the present value of the value of tax shields in \( t \) from the equation:

\[ VTS_0 = PV_0[T_{S,1}] + ... + PV_0[T_{S,t}] + \frac{VTS_0(1+g)^t}{(1+K_{VTS,1})(1+K_{VTS,2})...(1+K_{VTS,t})} \]

It is clear that:

\[ PV_0[VTS_t] = \frac{VTS_0(1+g)^t}{(1+K_{VTS,1})(1+K_{VTS,2})...(1+K_{VTS,t})} = PV_0[T_{S,t+1}] + ... = \sum_{t=1}^{\infty} PV_0[T_{S,t}] \]

\[ PV_0[VTS_t] = R_F T D_0 \sum_{t=1}^{\infty} \left[ \frac{1}{(1+R_F)^t} \right] + \frac{g[X^{t'-1}]}{(1+R_F)^{t+1}(1+\alpha)(X-1)} \]

We have three geometric progressions with different growth factors. The result is:

\[ PV_0[VTS_t] = \frac{T D_0}{(1+R_F)^t} \left[ \frac{g R_F X^t}{X-1} - \frac{g(1+R_F)}{(1+\alpha)(X-1)} \right] \]  
(A.22)

if \( \alpha = R_F \); \( X = (1+g) \) and \( PV_0[VTS_t] = \frac{R_F T D_0}{R_F - g} (1+g)^t / (1+R_F)^t \); \( (1+K_{VTS,t}) = (1+R_F) \)

To calculate the present value of the equity in \( t \), we start with equation  
(A.23)
\[ S_0 = \frac{ECF_0(1+g)}{(1+K_{e_1})} + \frac{ECF_0(1+g)^i}{(1+K_{e_1})...(1+K_{e_i})} + \frac{S_0(1+g)^i}{(1+K_{s_1})...(1+K_{s_i})} \quad (A.23) \]

It is clear that

\[ PV_0[S_1] = \frac{S_0(1+g)^i}{(1+K_{s_1})...(1+K_{s_i})} = \sum_{t=1}^{\infty} \frac{ECF_0(1+g)^i}{(1+K_{e_1})...(1+K_{e_i})} \]

From equation (24), we know that:

\[ PV_0[S_1] = \sum_{t=1}^{\infty} \frac{FCF_0(1+g)^i}{(1+K_{u})^i} + \sum_{t=1}^{\infty} \frac{D_0g(1+g)^{i-1}}{(1+\alpha)^i} - \sum_{t=1}^{\infty} \frac{D_0R_F(1-T)(1+g)^{i-1}}{(1+R_F)(1+K_{D_{1-i}})...(1+K_{D_{1-i}})} \quad (A.24) \]

(A.22) is also the sum of the present values of the tax shields from \( t+1 \) on, then, the last term of equation (A.24) is:

\[ PV_0[VTS_t] = \frac{1-T}{T} \frac{(1-T)D_0}{(1+R_F)^i} \left[ 1 + \frac{gR_F X^i}{(\alpha-g)(1+R_F)} - \frac{g(1+R_F)}{(1+\alpha)(X-1)} \right] \quad (A.25) \]

Calculating the sum of the two geometric progressions in (A.24) and using (A.25), we get:

\[ PV_0[S_1] = \frac{V_{u_0}(1+g)^i}{(1+K_{u})^i} + \frac{D_0gX^i}{(\alpha-g)(1+R_F)^i} - \frac{(1-T)D_0}{(1+R_F)^i} \left[ 1 + \frac{gR_F X^i}{(\alpha-g)(1+R_F)} - \frac{g(1+R_F)}{(1+\alpha)(X-1)} \right] \quad (A.26) \]

(A.26) may be simplified into:

\[ PV_0[S_1] = \frac{V_{u_0}(1+g)^i}{(1+K_{u})^i} + \frac{D_0g(1+g)^i}{(\alpha-g)(1+\alpha)^i} - \frac{(1-T)D_0}{(1+R_F)^i(\alpha-g)} \left[ \alpha + \frac{gR_F X^i(1)}{(X-1)} \right] \quad (A.27) \]

If \( \alpha = R_F \), (A.27) is:

\[ PV_0[S_1] = \frac{V_{u_0}(1+g)^i}{(1+K_{u})^i} - \frac{D_0(1+g)^i}{(1+R_F)^i} + \frac{D_0TR_F(1+g)^i}{(R_F-g)(1+R_F)^i} \]

If \( t = 0 \), (A.27) is:

\[ PV_0[S_1] = \frac{V_{u_0}(1+g)^i}{(1+K_{u})^i} + \frac{D_0\alpha T}{(\alpha-g)} + \frac{(1-T)D_0}{(1+R_F)^i(\alpha-g)} \left[ \alpha + \frac{gR_F X^i(1)}{(X-1)} \right] > \frac{V_{u_0}(1+g)^i}{(1+K_{u})^i} + \frac{D_0g(1+g)^i}{(\alpha-g)(1+\alpha)^i} \]
The present value of the unlevered equity in \( t \) is

\[
PV_0[Vu_t] = \frac{Vu_0(1 + g)^t}{(1 + Ku)^t}
\]  (A.28)

(A.27), (A.22), (A.21) and (A.28) satisfy the condition:

\[
PV_0[Vu_t] + PV_0[VTS_t] = PV_0[D_t] + PV_0[S_t]
\]

To calculate the discount rate of the expected equity cash flow in \( t \), we use equation (A.23):

\[
\frac{ECF_0(1 + g)^t}{(1 + Ke_1)(1 + Ke_t)} = PV_0[S_{t-1}] - PV_0[S_t]
\]  (A.29)

Using (A.27) and some algebra permits to find:

\[
(1 + Ke_1)...(1 + Ke_t) = \frac{S_0(Ku - g)}{(1 + Ku)^t} + \frac{D_0R_F(1 - T)}{(1 + g)^{t-1}(1 + R_F)^t} \left[ \frac{R_F - \alpha + g(1 + R_F)X^{t-1}}{g(1 + R_F) + R_F - \alpha} \right] + \frac{gD_0}{(1 + \alpha)^t}
\]  (A.30)

**The appropriate discount rate for the expected value of equity implied by Modigliani-Miller**

Calculating present value of equation (1) at \( t = 1 \):

\[
E_0[M_{0,1}, VTS_1] = E_0[M_{0,1} S_1] + E_0[M_{0,1} D_1] - E_0[M_{0,1} Vu_1]
\]

\[
VTS_0 \frac{(1 + g)}{(1 + R_F)} = S_0 \frac{(1 + g)}{(1 + Ku)} + D_0 \frac{(1 + g)}{(1 + Ku)} - Vu_0 \frac{(1 + g)}{(1 + Ku)}
\]

\[
\frac{S_0}{(1 + K_{St})} = \frac{S_0 + (VTS_0 - D_0)Ku + Vu_0R_F}{(1 + R_F)(1 + Ku)}
\]  (A.31)

\[
(1 + K_{St}) = (1 + R_F)(1 + Ku) \frac{(S_0 - Vu_0)(1 + Ku)^{t-1} + Vu_0(1 + R_F)^{t-1}}{(S_0 - Vu_0)(1 + Ku)^t + Vu_0(1 + R_F)^t}
\]  (A.32)

\[
\Pi(t)(1 + K_{St}) = \frac{S_0(1 + R_F)^t(1 + Ku)^t}{(S_0 - Vu_0)(1 + Ku)^t + Vu_0(1 + R_F)^t}
\]  (A.33)

**Present value of the expected increases of the book-value of equity**

Using equation (4), the present value of the future increases of equity is equal to the present value of the future increases of assets minus the present value of the future increases of debt. Therefore, the present value of the future increases of equity, according to the different theories is:
Appropriate discount rate for capital gains, $K_{CG}$

\[
P_{0}[S_1 - S_0]_{m=t=1} = \frac{S_0(1+g)}{1+K_{SI}} - \frac{S_0}{1+R_F} = gS_0 \left( \frac{1}{1+K_{CG}} \right)
\]

\[
\frac{1}{1+K_{CG}} = \frac{1+g}{g(1+K_{SI})} - \frac{1}{g(1+R_F)}
\]

According to Miles-Ezzell, as $K_{SI} = Ku$, (A.37) is:

\[
\frac{1}{1+K_{CG}} = \frac{1+g}{g(1+Ku)} - \frac{1}{g(1+R_F)}
\]

\[K_{CG} = Ku \text{ if } t>1. \text{ In our example, } K_{CG1} = -177.6\%.
\]

According to Modigliani-Miller, using (45), (A.37) is:

\[
\frac{1}{1+K_{CG}} = \frac{1}{(1+R_F)} - \frac{(Ke - R_F)(1+g)}{g(1+R_F)(1+Ku)}
\]

In our example, $K_{CG1} = -160.8\%.

If Debt is proportional to the Equity book value and the increase of assets is proportional to the free cash flow, using (40), (A.37) is:

\[
\frac{1}{1+K_{CG}} = \frac{1}{(1+Ku)} - \frac{Ke - R_F}{g(1+Ku)(1+R_F)}
\]

In our example, $K_{CG1} = -137.7\%.

The present value of the expected capital gain in $t$ is:

\[
P_{0}[S_t - S_0]_{m=t=1} = \frac{S_0(1+g)^t}{(1+K_{SI})...(1+K_{SI})} - \frac{S_0}{(1+R_F)^t} = gS_0(1+g)^{t-1} \left( \frac{1}{1+K_{CG1}} \right)...
\]
It is interesting to note that $K_{CGt}$ (except for $t = 1$) are equal for Miles-Ezzell and under the constant book-value leverage ratio.

**Total expected return for the shareholder**

The total expected return for the shareholder is $Ke$ in every period because

$$K_{SHARE} = \frac{gS_0 + ECF_o (1 + g)}{S_0} = \frac{gS_0 + S_o (Ke - g)}{S_o} = Ke$$

(A.42)
